Abstract. Various satellite-borne missions are being planned to measure the polarization of a large number of gamma-ray bursts (GRBs). We show that the polarization pattern resulting from the current models of GRB emission can be drastically modified by the existence of very light axion-like particles (ALPs), which are predicted by many extensions of the Standard Model of particle physics. Basically, the propagation of photons emitted by a GRB through cosmic magnetic fields with a domain-like structure induces photon-ALP mixing, which is expected to produce a strong modification of the initial photon polarization. Because of the random orientation of the magnetic field in each domain, this effect strongly depends on the orientation of the line of sight. As a consequence, photon-ALP conversion considerably broadens the initial polarization distribution. Searching for such a peculiar feature through future high-statistics polarimetric measurements therefore offers a new opportunity to discover very light ALPs.

Keywords: axions, gamma-ray burst polarization.

1. Introduction

A generic feature of many extensions of the Standard Model is the prediction of axion-like particles (ALPs), namely very light spin-zero bosons characterized by a two-photon coupling $a\gamma\gamma$. Besides occurring in four-dimensional models [1, 2, 3, 4], ALPs naturally arise within compactified Kaluza-Klein theories [5] as well as in superstring theories [6, 7]. As the name itself suggests, ALPs are a generalization of the axion, the pseudo-Goldstone boson associated with the Peccei-Quinn symmetry proposed as a natural solution to the strong CP problem [8, 9, 10, 11, 12]. Specifically, while the axion is characterized by a strict relationship between its mass and $a\gamma\gamma$ coupling constant, these two parameters are to be regarded as independent for ALPs [13]. Depending on the actual values of their mass and $a\gamma\gamma$ coupling constant, ALPs can play an important role in cosmology, either as cold dark matter particles responsible for the structure formation in the Universe [14] or as quintessential dark energy [15] which presumably triggers the present accelerated cosmic expansion (see [16] for a recent review on ALPs).

Owing to the $a\gamma\gamma$ coupling, in an external electromagnetic field the phenomenon of photon-ALP mixing takes place[‡]. More specifically, two very interesting effects arise in such a situation. One is photon-ALP conversion (oscillation) [17, 18, 19], which is exploited by the ADMX experiment to search for ALP dark matter [20], by CAST to search for solar axions [21, 22, 23] and by the regeneration laser experiments [24, 25, 26, 27, 28, 29, 30]. The other effect consists in the change of the polarization state of photons traveling in a magnetic field. In particular, an initially linearly polarized photon beam propagating in a transverse magnetic field acquires an elliptical polarization with the major axis rotated with respect to the direction of the initial polarization [17, 31, 32]. A claim for a positive observational evidence of such an effect by the PVLAS collaboration [33] employing a laser beam has subsequently been withdrawn [34].

Laboratory experiments devised to search for an ALP-induced photon beam polarization suffer from the intrinsic limitation that a very short baseline is available. Remarkably enough, astrophysical observations of distant X-ray and γ -ray sources offer new opportunities to look for ALP effects in polarization measurements (see [35] for a recent comprehensive study). Actually, several satellite-borne missions are currently under consideration to perform the challenging measurement of the polarization state of photons emitted by distant astrophysical X-ray and γ -ray sources like the gamma-ray bursts (GRBs) in the keV-MeV energy range. These new missions have a wide field of view and a broad energy band, thereby guaranteeing polarimetric measurements of GRBs to be performed with high statistics. Such a circumstance evidently allows for a reliable determination of the statistical properties of the GRB polarization, which has recently been proposed as a crucial tool to discriminate among different models for the GRB emission [36].

[‡] We stress that the external field is necessary in order to compensate for the photon-ALP spin mismatch.

We show that strong modifications in the polarization pattern of distant X-ray and γ -ray sources can be produced by ALPs with parameters lying in experimentally allowed ranges. Basically, the following situation is envisaged. Photons are emitted by the considered sources at cosmological distances and on their way to us they cross different magnetic field configurations, which ought to induce photon-ALP mixing. Consequently, the initial photon polarization gets changed and this change can eventually be detected.

Manifestly, the role of the magnetic field is crucial in this respect and we have to contemplate all kinds of magnetic field configurations that the photon beam can experience, namely the magnetic field inside the source, the extragalactic magnetic field, the Galactic magnetic field and possibly an intracluster magnetic field if the beam crosses a cluster of galaxies. All these magnetic field components have a quite complicated and poorly known morphology, so that it has become customary to suppose that they possess a domain-like structure with varying coherence lengths. Therefore, we are actually dealing with a long baseline astrophysical setup to study ALP effects on the polarization of X-ray and γ -ray photons from distant sources. Our aim is indeed to investigate under which circumstances these effects are sizeable and detectable. For definiteness, our attention will be focussed on GRBs but our conclusions apply to any far-away astrophysical source of photons in the keV-MeV energy range, among which blazars play a very important role. We stress that at variance with a previous analysis of similar effects concerning radio sources [37] our picture does not require the actual presence of an ALP cosmological background in the Universe but merely demands that ALPs are produced by photon oscillations.

The plan of the paper is as follows. In Section 2 we discuss the perspectives and the expectations for the measurement of GRB polarization. In Section 3 we review the mechanism of photon-ALP mixing in random magnetic fields which is relevant for our physical case and we identify the allowed ranges of the parameters that determine the effect in question. In Section 4 we discuss the impact of photon-ALP mixing on the polarization of GRBs for various intervening magnetic field configurations. We find that photon-ALP mixing in the magnetic field of GRBs is strongly suppressed. Still, during photon propagation from the source to us a sizeable mixing can occur. Due to the randomness of crossed magnetic fields, photon-ALP mixing depends strongly on the orientation of the line of sight. As a consequence, this effect is expected to produce a peculiar broad distribution in the polarization of GRBs with different projected position on the sky. Thus, the detection of such a feature through future high-statistics polarimetric measurements can become a new strategy to look for the existence of ALPs with very low mass. Finally, in Section 5 we offer a discussion of our results as well as of the possible further developments in this field.

2. Gamma-ray burst polarization measurements

GRBs are brief, intense flashes of γ -rays originating at cosmological distances and they are the most luminous objects in the Universe. Presently available lightcurves and

spectral observational information fail to provide a unique answer concerning their emission mechanism, and the polarization measurements of their X -ray and γ -ray emission have been recognized as a crucial mean to shed light on the inner structure of GRBs, including the geometry and the physical processes occurring close to the central engine.

To date, GRB polarization measurements have been carried out systematically only in the optical band and in the afterglow phase. Sensitive observational techniques for X -ray and γ -ray polarimetry are being developed and in the next few years various polarimetric missions can finally enable to measure the X -ray and γ -ray polarization of the GRB emission. The missions presently under consideration include *POET* (Polarimeters for Energetic Transients) [38], *PoGO* (Polarimeter of Gamma-ray Observer) [39], *POLAR* [40], *GEMS* (Gravity and Extreme Magnetism) [41], *XPOL* [42], *GRIPS* (Gamma-Ray Burst Investigation via Polarimetry and Spectroscopy) [43] and *NHXM* (New Hard X-ray Mission) [44].

In particular, *POET* is the only one that incorporates a broadband capability for measuring the prompt GRB emission and employs two different polarimeters, both with a wide field of view: *GRAPE* (Gamma-Ray Polarimeter Experiment) operating between 60 keV and 500 keV and *LEP* (Low Energy Polarimeter) operating between 2 keV and 500 keV. Two smaller mission concepts based on the *POET* instruments are already scheduled for launch: *GRAPE* and *GRBP* (Gamma-Ray Burst Polarimeter, a smaller version of LEP). Both instruments offer the opportunity for a first glimpse at the polarization of prompt GRB emission and in fact *POET* provides sufficient sensitivity and sky coverage to detect up to 200 GRBs in a two-years mission.

In general, given a random distribution of viewing angles, a statistical study of the polarization properties of a large sample of GRBs should allow to discriminate among different emission models and can provide a direct diagnostic tool for the magnetic field structure, the radiation mechanism and the geometric configuration of GRB jets. Toma *et al.* [36] display the predictions for the distribution of the amount of linear polarization in three different models: synchrotron emission with ordered magnetic fields (SO), synchrotron emission in random magnetic fields (SR) and Compton-drag model (CD). Specifically, the ratio N_m/N_d of the number N_m of GRBs for which the degree of polarization can be measured to the number N_d of GRBs that are detected, and the distribution of the degree of linear polarization Π_L , can be used as criteria. It turns out that if $N_m/N_d > 30\%$ and Π_L clusters between 0.2 and 0.7, then the SO model will be favored. If instead $N_m/N_d < 15\%$, then both the SR and the CD model will be preferred. Finally, if several events with $\Pi_L > 0.8$ are observed, then the CD model will instead be singled out.

We will show that the presence of ALPs mixing with photons in astrophysical magnetic fields can drastically affect such expected statistical distributions for the linear polarization of GRBs.

3. Photon-ALP mixing in random magnetic fields

3.1. Equations of motion

The Lagrangian describing the photon-ALP system is

$$\mathcal{L} = \mathcal{L}_\gamma + \mathcal{L}_a + \mathcal{L}_{a\gamma} . \quad (1)$$

The QED Lagrangian for photons is

$$\mathcal{L}_\gamma = -\frac{1}{4}F_{\mu\nu}F^{\mu\nu} + \frac{\alpha^2}{90m_e^4} \left[(F_{\mu\nu}F^{\mu\nu})^2 + \frac{7}{4} (F_{\mu\nu}\tilde{F}^{\mu\nu})^2 \right] , \quad (2)$$

where $F_{\mu\nu} \equiv (\mathbf{E}, \mathbf{B})$ is the electromagnetic field tensor, $\tilde{F}_{\mu\nu} = \frac{1}{2}\epsilon_{\mu\nu\rho\sigma}F^{\rho\sigma}$ is its dual, α is the fine-structure constant and m_e is the electron mass. Natural Lorentz-Heaviside units with $\hbar = c = k_B = 1$ are employed throughout. The second term on the r.h.s. of Eq. (2) is the Euler-Heisenberg-Weisskopf (HEW) effective Lagrangian [17], which accounts for the one-loop corrections to classical electrodynamics. The Lagrangian for the noninteracting ALP field a is

$$\mathcal{L}_a = \frac{1}{2}\partial^\mu a \partial_\mu a - \frac{1}{2}m^2 a^2 , \quad (3)$$

where m is the ALP mass. A general feature of ALP models is the CP-conserving pseudo-scalar two-photon coupling, so that the photon-ALP interaction is represented by the following Lagrangian [17]

$$\mathcal{L}_{a\gamma} = -\frac{1}{4}g_{a\gamma}F_{\mu\nu}\tilde{F}^{\mu\nu}a = g_{a\gamma}\mathbf{E} \cdot \mathbf{B} a , \quad (4)$$

where $g_{a\gamma}$ is the photon-ALP coupling constant (which has the dimension of an inverse energy). It is always assumed $g_{a\gamma} \ll G_F^{1/2}$ and $m \ll G_F^{-1/2}$, with $G_F^{-1/2} \simeq 250 \text{ GeV}$ denoting the Fermi scale of weak interactions.

We shall be concerned throughout with a monochromatic photon/ALP beam of energy E propagating along the z -direction in the presence of a magnetic field $\mathbf{B}$. Clearly, the beam propagation is described by the second-order coupled generalized Klein-Gordon and Maxwell equations arising from the Lagrangian in Eq. (1). However, since we are interested in the regime $E \gg m$ the short-wavelength approximation can be applied successfully and turns the beam propagation equation into the following Schrödinger-like one [17]

$$\left(i \frac{d}{dz} + E + \mathcal{M} \right) \begin{pmatrix} A_x(z) \\ A_y(z) \\ a(z) \end{pmatrix} = 0 , \quad (5)$$

where $A_x(z)$ and $A_y(z)$ are the two photon linear polarization amplitudes along the x and y axis, respectively, $a(z)$ denotes the ALP amplitude and $\mathcal{M}$ represents the photon-ALP mixing matrix.

For our further purposes, it is more convenient to work with the polarization density matrix

$$\rho(z) = \begin{pmatrix} A_x(z) \\ A_y(z) \\ a(z) \end{pmatrix} \otimes \begin{pmatrix} A_x(z) & A_y(z) & a(z) \end{pmatrix}^* \quad (6)$$

which obeys the Liouville-Von Neumann equation

$$i \frac{d\rho}{dz} = [\rho, \mathcal{M}] \quad (7)$$

associated with Eq. (5). We denote by $T(z, z_0)$ the transfer function, namely the solution of Eq. (5) with initial condition $T(z_0, z_0) = 1$. Then any solution of Eq. (7) can be represented as

$$\rho(z) = T(z, z_0) \rho(z_0) T^\dagger(z, z_0) . \quad (8)$$

The mixing matrix $\mathcal{M}$ takes a simpler form if we restrict our attention to the case of a photon beam propagating in a single magnetic domain, where the magnetic field $\mathbf{B}$ is supposed to be homogeneous. We denote by $\mathbf{B}_T$ the transverse magnetic field, namely its component in the plane normal to the beam direction. We can choose the y -axis along $\mathbf{B}_T$ so that B_x vanishes. Under these simplifying assumptions, the mixing matrix can be written as [45]

$$\mathcal{M}^{(0)} = \begin{pmatrix} \Delta_\perp & 0 & 0 \\ 0 & \Delta_\parallel & \Delta_{a\gamma} \\ 0 & \Delta_{a\gamma} & \Delta_a \end{pmatrix} , \quad (9)$$

whose elements are [17]

$$\Delta_\parallel \equiv \Delta_{\text{pl}} + 3.5 \Delta_{\text{QED}} , \quad (10)$$

$$\Delta_\perp \equiv \Delta_{\text{pl}} + 2 \Delta_{\text{QED}} , \quad (11)$$

$$\Delta_{a\gamma} \equiv \frac{1}{2} g_{a\gamma} B_T \simeq 1.52 \times 10^{-2} \left(\frac{g_{a\gamma}}{10^{-11} \text{ GeV}^{-1}} \right) \left(\frac{B_T}{10^{-9} \text{ G}} \right) \text{ Mpc}^{-1} , \quad (12)$$

$$\Delta_a \equiv -\frac{m^2}{2E} \simeq -7.8 \times 10^{-3} \left(\frac{m}{10^{-13} \text{ eV}} \right)^2 \left(\frac{E}{10^2 \text{ keV}} \right)^{-1} \text{ Mpc}^{-1} , \quad (13)$$

with

$$\Delta_{\text{pl}} \equiv -\frac{\omega_{\text{pl}}^2}{2E} \simeq -1.1 \times 10^{-4} \left(\frac{E}{10^2 \text{ keV}} \right)^{-1} \left(\frac{n_e}{10^{-7} \text{ cm}^{-3}} \right) \text{ Mpc}^{-1} , \quad (14)$$

$$\Delta_{\text{QED}} \equiv \frac{\alpha E}{45\pi} \left(\frac{B_T}{B_{\text{cr}}} \right)^2 \simeq 4.1 \times 10^{-16} \left(\frac{E}{10^2 \text{ keV}} \right) \left(\frac{B_T}{10^{-9} \text{ G}} \right)^2 \text{ Mpc}^{-1} , \quad (15)$$

where n_e is the electron density in the medium, $\omega_{\text{pl}}^2 = 4\pi\alpha n_e/m_e$ is the associated plasma frequency, $B_{\text{cr}} \equiv m_e^2/e \simeq 4.41 \times 10^{13} \text{ G}$ is the critical magnetic field and e denotes the electron charge.

3.2. Input parameters

Before proceeding further, we find it convenient to discuss the ranges of the parameters entering our scenario. The strength of the widespread, all-pervading magnetic field in the extragalactic medium has to meet the constraint $B \lesssim 2.8 \times 10^{-7} (L/\text{Mpc})^{-1/2} \text{ G}$ – where L denotes its coherence length – which arises by scaling the original bound from the Faraday effect of distant radio sources [46, 47] to the now much better known baryon density measured by the Wilkinson Microwave Anisotropy Probe (WMAP) mission [48]. Its coherence length is expected to lie in the range $1 \text{ Mpc} < L < 10 \text{ Mpc}$ [49]. The mean diffuse intergalactic plasma density is bounded by $n_e \lesssim 2.7 \times 10^{-7} \text{ cm}^{-3}$, corresponding to the WMAP measurement of the baryon density [48]. Recent results from the CAST experiment yield a direct bound on the photon-ALP coupling constant $g_{a\gamma} \lesssim 8.8 \times 10^{-11} \text{ GeV}^{-1}$ for $m \lesssim 0.02 \text{ eV}$ [23], slightly better than the long-standing globular-cluster limit [50]. In addition, for $m \lesssim 10^{-10} \text{ eV}$ a more stringent limit arises from the absence of γ -rays from SN 1987A, giving $g_{a\gamma} \lesssim 1 \times 10^{-11} \text{ GeV}^{-1}$ [51, 52] even if with a large uncertainty§.

3.3. Mixing in a single magnetic domain

Inside a single magnetic domain $\mathbf{B}$ is homogeneous. Then it is straightforward to check that $\mathcal{M}^{(0)}$ in Eq. (9) can be brought into a diagonal form

$$D = \begin{pmatrix} D_1 & 0 & 0 \\ 0 & D_2 & 0 \\ 0 & 0 & D_3 \end{pmatrix} \quad (16)$$

by the similarity transformation

$$D = W \mathcal{M}^{(0)} W^\dagger \quad (17)$$

with

$$W = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos \theta & \sin \theta \\ 0 & -\sin \theta & \cos \theta \end{pmatrix}, \quad (18)$$

where the mixing angle θ is given by

$$\theta = \frac{1}{2} \arctan \left(\frac{2\Delta_{a\gamma}}{\Delta_{\parallel} - \Delta_a} \right) \quad (19)$$

and explicitly we get

$$D_1 = \Delta_{\perp}, \quad (20)$$

$$D_2 = \frac{(\Delta_{\parallel} + \Delta_a)}{2} + \frac{1}{2} [(\Delta_a - \Delta_{\parallel})^2 + 4\Delta_{a\gamma}^2]^{1/2}, \quad (21)$$

§ These bounds on ALPs can be relaxed if they have a chameleontic nature [53], in which case the most stringent constraint comes from the observed starlight polarization and reads $g_{a\gamma} \lesssim 10^{-9} \text{ GeV}^{-1}$ [35]. However, we do not commit ourselves to chameleontic ALPs.

$$D_3 = \frac{(\Delta_{\parallel} + \Delta_a)}{2} - \frac{1}{2} [(\Delta_a - \Delta_{\parallel})^2 + 4\Delta_{a\gamma}^2]^{1/2}. \quad (22)$$

So, we find that the transfer matrix is presently

$$T^{(0)}(z, z_0) = W^\dagger e^{iD(z-z_0)} W. \quad (23)$$

Finally, the density matrix can be computed by means of the general formula in Eq. (8).

The probability that a photon initially polarized along the y axis ($\rho_{22}(0) = 1$) converts into an ALP after a distance d then reads [17]

$$P_{a\gamma}^{(0)} = \rho_{33}(d) = \sin^2 2\theta \sin^2 \left(\frac{\Delta_{\text{osc}} d}{2} \right), \quad (24)$$

where the oscillation wave number is

$$\Delta_{\text{osc}} = \left[(\Delta_a - \Delta_{\parallel})^2 + 4\Delta_{a\gamma}^2 \right]^{1/2}. \quad (25)$$

Experience with problems similar to the one considered here shows that it proves useful to define a *low critical energy* [54]

$$E_L \equiv \frac{E |\Delta_a - \Delta_{\text{pl}}|}{2\Delta_{a\gamma}} \simeq \frac{25 |m^2 - \omega_{\text{pl}}^2|}{(10^{-13} \text{eV})^2} \left(\frac{10^{-9} \text{G}}{B_T} \right) \left(\frac{10^{-11} \text{GeV}^{-1}}{g_{a\gamma}} \right) \text{keV} \quad (26)$$

along with a *high critical energy* [55]

$$E_H \equiv \frac{90\pi g_{a\gamma} B_{\text{cr}}^2}{7\alpha B_T} \simeq 2.1 \times 10^{15} \left(\frac{10^{-9} \text{G}}{B_T} \right) \left(\frac{g_{a\gamma}}{10^{-11} \text{GeV}^{-1}} \right) \text{keV}. \quad (27)$$

It is easy to see that the oscillation wave number can be expressed in terms of E_L and E_H as

$$\Delta_{\text{osc}} = 2\Delta_{a\gamma} \left\{ 1 + \left[\text{sgn}(m_a - \omega_{\text{pl}}) \left(\frac{E_L}{E} \right) + \left(\frac{E}{E_H} \right) \right]^2 \right\}^{1/2} \quad (28)$$

and from Eqs. (19), (24), (25) and (28) it follows that in the energy range $E_L \ll E \ll E_H$ the photon-ALP mixing is maximal ($\theta \simeq \pi/4$) and the conversion probability becomes energy-independent. This is the so-called *strong-mixing regime*. Outside this regime the conversion probability turns out to be energy-dependent and vanishingly small, so that E_L and E_H acquire the meaning of low-energy and high-energy energy cut-off, respectively.

3.4. Photon transfer function and polarization

As stressed in Section 1, the magnetic field crossed by the beam on its way from the source to us is modelled as a network of magnetic domains. For each magnetic field component (source, extragalactic, intracluster and Galactic) all domains are supposed to have the same size L equal to the coherence length and in every domain the magnetic field $\mathbf{B}$ is assumed to have the same strength but its direction is allowed to change randomly from one domain to another.

As a matter of fact, the application of this approach to extragalactic magnetic fields neglects cosmological effects which are potentially important, since the GRB polarization can be measured for sources out to a redshift of about 2||. However, for

|| Private communication from E. Costa and K. Toma.

the sake of clarity – and even because this effect is irrelevant outside cosmology – we present below the investigation of the photon-ALP mixing in the above random network discarding redshift-dependent complications, which will be discussed in Subsection 3.5.

In order to accomplish our task, we take the x, y, z coordinate system as *fixed* once and for all, denoting by ψ the angle between $\mathbf{B}_T$ and the y axis in a generic domain and treating ψ as a *random variable* in the range $0 \leq \psi < 2\pi$.

So, what we need in the first place is the generalization of the previous result for an arbitrary orientation of $\mathbf{B}_T$ in a single domain. Clearly, the mixing matrix $\mathcal{M}$ presently arises from $\mathcal{M}^{(0)}$ through the similarity transformation

$$\mathcal{M} = V^\dagger(\psi) \mathcal{M}^{(0)} V(\psi) \quad (29)$$

operated by the rotation matrix in the x - y plane, namely

$$V(\psi) = \begin{pmatrix} \cos \psi & -\sin \psi & 0 \\ \sin \psi & \cos \psi & 0 \\ 0 & 0 & 1 \end{pmatrix}. \quad (30)$$

Accordingly we find [45]

$$\mathcal{M} = \begin{pmatrix} \Delta_{xx} & \Delta_{xy} & \Delta_{a\gamma} \sin \psi \\ \Delta_{yx} & \Delta_{yy} & \Delta_{a\gamma} \cos \psi \\ \Delta_{a\gamma} \sin \psi & \Delta_{a\gamma} \cos \psi & \Delta_a \end{pmatrix}, \quad (31)$$

with

$$\Delta_{xx} = \Delta_{\parallel} \sin^2 \psi + \Delta_{\perp} \cos^2 \psi, \quad (32)$$

$$\Delta_{xy} = \Delta_{yx} = (\Delta_{\parallel} - \Delta_{\perp}) \sin \psi \cos \psi, \quad (33)$$

$$\Delta_{yy} = \Delta_{\parallel} \cos^2 \psi + \Delta_{\perp} \sin^2 \psi. \quad (34)$$

Our next step consists in the evaluation of the transfer matrix in the considered domain. As before, our strategy is to diagonalize the mixing matrix. Dealing with $\mathcal{M}$ is slightly more complicated than dealing with $\mathcal{M}^{(0)}$, but Eq. (29) allows to reduce the present problem to the one solved above [56]. It is convenient to label all quantities pertaining to the generic k -th domain with the index k , with the understanding that all z -dependent quantities labelled by k are evaluated at the edge of the k -th domain closer to us. The source is located at $z = 0$ and we suppose that there are N magnetic domains with size L along the line of sight. Hence, the beam propagation over the k -th domain is described by the polarization density matrix

$$\rho_k = T_k \rho_{k-1} T_k^\dagger, \quad (35)$$

where the transfer matrix T_k can be rewritten as

$$T_k = V^\dagger(\psi_k) W^\dagger e^{iDL} W V(\psi_k), \quad (36)$$

where ψ_k is the random value of ψ in the domain in question. The explicit form of T_k can be represented as

$$T_k = e^{iD_1 L} T_A(\psi_k) + e^{iD_2 L} T_B(\psi_k) + e^{iD_3 L} T_C(\psi_k), \quad (37)$$

with

$$T_A(\psi_k) \equiv \begin{pmatrix} \cos^2 \psi_k & -\sin \psi_k \cos \psi_k & 0 \\ -\sin \psi_k \cos \psi_k & \sin^2 \psi_k & 0 \\ 0 & 0 & 0 \end{pmatrix}, \quad (38)$$

$$T_B(\psi_k) \equiv \begin{pmatrix} \sin^2 \psi_k \cos^2 \theta & \sin \psi_k \cos \psi_k \cos^2 \theta & \sin \theta \cos \theta \sin \psi_k \\ \sin \psi_k \cos \psi_k \cos^2 \theta & \cos^2 \psi_k \cos^2 \theta & \sin \theta \cos \theta \cos \psi_k \\ \sin \psi_k \cos \theta \sin \theta & \cos \psi_k \sin \theta \cos \theta & \sin^2 \theta \end{pmatrix}, \quad (39)$$

$$T_C(\psi_k) \equiv \begin{pmatrix} \sin^2 \theta \sin^2 \psi_k & \sin^2 \theta \sin \psi_k \cos \psi_k & -\sin \theta \cos \theta \sin \psi_k \\ \sin^2 \theta \sin \psi_k \cos \psi_k & \sin^2 \theta \cos^2 \psi_k & -\sin \theta \cos \theta \cos \psi_k \\ -\sin \theta \cos \theta \sin \psi_k & -\sin \theta \cos \theta \cos \psi_k & \cos^2 \theta \end{pmatrix}. \quad (40)$$

Altogether, the whole beam propagation from the source to us is described by

$$\rho_N = T(\psi_N, \dots, \psi_1) \rho_0 T^\dagger(\psi_N, \dots, \psi_1), \quad (41)$$

where ρ_0 is the polarization density matrix at emission and we have set

$$T(\psi_N, \dots, \psi_1) \equiv \prod_{k=1}^N T_k. \quad (42)$$

Finally, the 2×2 photon polarizaton density matrix (i.e. the 1-2 block of the density matrix for the photon-ALP system) can be expressed in terms of the Stokes parameters as [57]

$$\rho_\gamma = \frac{1}{2} \begin{pmatrix} I + Q & U - iV \\ U + iV & I - Q \end{pmatrix} \quad (43)$$

and the degree of *linear polarization* Π_L is defined as [58]

$$\Pi_L \equiv \frac{(Q^2 + U^2)^{1/2}}{I} = \frac{[(\rho_{11} - \rho_{22})^2 + (\rho_{12} - \rho_{21})^2]^{1/2}}{\rho_{11} + \rho_{22}}. \quad (44)$$

In the following, we will evaluate the ALP contribution to Π_L in the various physical situations mentioned above.

3.5. Effects of the cosmic expansion

As explained in the previous Subsection 3.4, the considered strategy has to be slightly revised in order to account for the cosmic expansion when considering photon propagation in the extragalactic magnetic fields. In practice, the logic remains the same but distances have to be parameterized in term of the redshift z rather than by the coordinate along the propagation direction[¶]. As is well known, the distance $dl(z)$ travelled by a photon over an infinitesimal redshift interval dz is expressed by the relation

$$dl(z) = \frac{dz}{H_0 (1+z) \left[(1+z)^2 (\Omega_M z + 1) - \Omega_\Lambda z (z+2) \right]^{1/2}}, \quad (45)$$

[¶] In the present Subsection, z denotes from now on the redshift rather than the z -coordinate, and so no confusion will arise.

where for the standard Λ CDM cosmological model we have $H_0 \simeq 72 \text{ Kms}^{-1} \text{ Mpc}^{-1}$ for the Hubble constant, while $\Omega_M \simeq 0.3$ and $\Omega_\Lambda \simeq 0.7$ represent the average cosmic density of matter and dark energy, respectively, in units of the critical density $\rho_{\text{cr}} \simeq 0.92 \cdot 10^{-29} \text{ g cm}^{-3}$ [59]. Hence, a generic domain extending over the redshift interval $[z_a, z_b]$ ($z_a < z_b$) has size

$$L(z_a, z_b) \simeq 4.17 \int_{z_a}^{z_b} \frac{dz}{(1+z) \left[(1+z)^2 (0.3z+1) - 0.7z(z+2) \right]^{1/2}} \text{ Gpc}. \quad (46)$$

After photons have been emitted by a GRB, they propagate in the intergalactic medium (IGM). Within the present context, it looks natural to describe the overall structure of the cellular configuration of the extragalactic magnetic field by a *uniform* mesh in redshift space, which can be constructed as follows. In the lack of any reliable information, we assume for definitiveness $L_0 = 1 \text{ Mpc}$ as coherence length of the magnetic field B at redshift $z = 0$, which in our notation translates into

$$L(0, z_1) = 1 \text{ Mpc}, \quad (47)$$

which fixes the size in redshift space of the domain closest to us through Eq. (46). Actually, since we are employing a uniform mesh in redshift space, z_1 sets the size of *all* magnetic domains by recursive application of Eq. (46). Hence, the n -th one extends from $z = (n-1)z_1$ to $z = nz_1$ and its length can be written as $L((n-1)z_1, nz_1)$.

The absence of the Gunn-Peterson effect is usually taken as evidence that the IGM is ionized. The high electrical conductivity of the IGM allows us to assume that the electron number density n_e traces the cosmic matter distribution. But since n_e is proportional to the mass density ρ and the average number density of electrons $\bar{n}_e$ goes like $(1+z)^3$, we obtain relationship

$$n_e(z) = (1 + \delta(z)) \bar{n}_{e,0} (1+z)^3, \quad (48)$$

where $\delta(z) \equiv (\rho(z) - \bar{\rho}(z))/\bar{\rho}(z)$ is the mass density contrast, which quantifies the local deviation of the matter density from the average and can be computed starting from a given spectrum of density perturbations (see, e.g. [56]). Actually, two facts follow at once. First, the ionized nature of the IGM implies that the plasma frequency varies with z as

$$\omega_{\text{pl}} = (1 + \delta(z))^{1/2} \bar{\omega}_{\text{pl},0} (1+z)^{3/2} \quad (49)$$

owing to its dependence on n_e ($\bar{\omega}_{\text{pl},0}$ obviously corresponds to $\bar{n}_{e,0}$). Second, because of the resulting high conductivity of the IGM, the magnetic flux lines can be thought as frozen in the IGM. Therefore, flux conservation during the cosmic expansion entails that B scales like $n_e^{2/3}$, thereby implying the magnetic field in the domain at redshift z is

$$B = (1 + \delta(z))^{2/3} \bar{B}_0 (1+z)^2, \quad (50)$$

where $\bar{B}_0$ denotes the average magnetic field at $z = 0$.

As a rule, simulations of the mass distribution in the Universe predict that most of the considered domains should be under-dense with respect to the mean by a factor

~ 10 [60, 61]. Simulations as well as observations also show the existence of over-dense regions with respect to the mean by a factor $10 - 100$ at low redshift [62], and Eq. (50) entails that in the latter regions the magnetic field should be larger by a factor $\sim 5-20$. However, the characteristic size of such over-dense regions turns out to be $\lesssim 100$ kpc, and so they fill only a small fraction of space [63]. As a consequence, the overall effect of these over-dense regions on photon-ALP mixing is negligible: ignoring them effectively amounts to take the source slight nearer and nothing else. We are therefore led for simplicity to discard matter overdensity effects, thereby setting $\delta(z) = 0$. In this way, we also avoid committing ourselves with any specific (model-dependent) choice for the matter density distribution. Hence, in the following we will simply assume $B \simeq \bar{B}_0 (1+z)^2$, where for definitiveness we will take $\bar{B}_0 = 10^{-9}$ G as average value of the magnetic field at $z = 0$.

Moreover, the exact value of ω_{pl} and its scaling with the redshift [Eq. (49)] can also be safely neglected. The reason is that we are working within the strong-mixing regime, in which plasma effects are irrelevant, and so our result is independent of the precise value of ω_{pl} in every magnetic domain: all what matters is that the strong-mixing condition is met in any domain and we have checked that for our preferred values of the input parameters this is indeed the case. Finally, we remark that another consequence of the strong-mixing regime is that photon-ALP mixing is energy-independent, and so we do not have to worry about the change of the photon energy along the line of sight caused by the cosmic expansion.

4. ALP effects on the polarization of gamma-ray sources

Equipped with the results of the previous Section, we are now ready to investigate the implications of photon-ALP mixing on the polarization of GRBs. Needless to say, we also have to keep the photon-ALP conversion probability under control in order to make sure that the resulting dimming does not prevent the source from being detected. As far as the magnetic field is concerned, we will address in turn the various configurations crossed by the beam, namely the component inside the source, the extragalactic and the intracluster contributions and the Galactic component. For definiteness, we shall take $g_{a\gamma} = 10^{-11} \text{ GeV}^{-1}$ throughout.

4.1. Source magnetic field

The relevance of ALP-induced polarization in the source magnetic field for the GRB emission has been studied in [64]. In that paper, the authors claim a potentially large effect. Lacking a detailed model for the GRB environment, we follow [64] and we consider the source as a region where the magnetic field is homogeneous, with strength $B \simeq 10^9$ G and size $L \simeq 10^9$ cm. The typical electron number density in the source is estimated as $n_e \simeq 10^{10} \text{ cm}^{-3}$. Accordingly, from Eq. (27) we find the the high-energy cut-off (arising from QED vacuum polarization) is $E_H \simeq 2 \times 10^{-3} \text{ keV}$, regardless of

m . Thus – contrary to the previous claim – in this situation ALPs do not affect the GRB polarization. However, this model for the source is oversimplified and in particular the magnetic field could have a turbulent and irregular structure. Since there are large uncertainties in the parameters of the GRB emitting regions, it would be premature to exclude definitively the possibility of any effect of ALP conversions in the source. However, lacking of a detailed model for the GRB emitting region, hereafter we neglect possible photon-ALP conversions occurring in the source.

4.2. Extragalactic magnetic field

Once emitted by a GRB, photons propagate in the IGM, which is modelled as explained in Subsection 3.5. Our results can be summarized as follows.

In Figure 1 we show the average final linear polarization Π_L as a function of the photon energy E , starting with a completely unpolarized source at distance $d = 100$ Mpc. The averaging process is over an ensemble of 10^4 realizations of the random magnetic field network. Since in this case we are considering a relatively close source, we neglect the redshift dependence of the extragalactic magnetic field. In agreement with Eq. (26), we find that ALP effects on the polarization start to become relevant at $E \simeq 25$ keV for $m = 10^{-13}$ eV and at $E \simeq 2.5$ keV for $m = 10^{-14}$ eV. Moreover, ALP effects saturate fast as we enter the strong-mixing regime, where the photon-ALP conversion probability is energy-independent. A similar trend concerns the photon survival probability $P_{\gamma\gamma}$. In the following, we will focus on the strong-mixing regime, choosing $E = 100$ keV as observed reference photon energy and $m = 10^{-13}$ eV as reference ALP mass.

In Figure 2 we exhibit the average linear polarization Π_L and the photon survival probability $P_{\gamma\gamma}$ as a function of the source distance d , starting from a source fully polarized along the x direction ($\rho_{xx}(0) = 1$). Again, the averaging process is over an ensemble of 10^4 realizations of the random magnetic field network. For our input values, we get $\Delta_{a\gamma} L \ll 1$ in every magnetic domain, so that the conversion probability in a single domain dictated by Eq. (24) assumes the form $P_{a\gamma}^{(0)} = (\Delta_{a\gamma} L)^2$. In this limit, neglecting the redshift dependence in the extragalactic magnetic field, the average photon survival probability reduces to the simple analytic expression [45, 65]

$$P_{\gamma\gamma}(d) = \frac{2}{3} + \frac{1}{3} \exp\left(-\frac{3P_{a\gamma}^{(0)}d}{L}\right), \quad (51)$$

thereby implying on average a complete equipartition of the photon/ALP ensemble after passage through many domains ($d \gg L$). As a check of our numerical simulations, in Figure 2 we also compare the numerical (dashed curve) and the analytical (continuous curve) results for $P_{\gamma\gamma}(d)$. The nice agreement between the two prescriptions reassures us about the reliability of our simulations. We find that the average photon survival probability saturates at $2/3$ for $d \gtrsim 500$ Mpc. Instead, the saturation of the average final linear polarization occurs at a larger distance $d \gtrsim 10^3$ Mpc with asymptotic value $\Pi_L \simeq 0.79$. Furthermore, an important conclusion to be drawn from Figure 2 is that

Figure 1. Average final linear polarization Π_L as a function of the photon energy E after propagation in the extragalactic magnetic field for ALP masses $m = 10^{-13}$ eV (solid line) and $m = 10^{-14}$ eV (dashed line), respectively. The emitting GRB is assumed to be completely unpolarized and at distance $d = 100$ Mpc.

the dimming arising from photon-ALP conversion never prevents the observation of the gamma-ray flux.

In Figures 3, 4, 5 and 6 we display the final probability density functions f_Π for the GRB linear polarization, assuming that all sources are at redshift $z = 0.03$, $z = 0.3$, $z = 1$ and $z = 2$, respectively. From our Eq. (46), these redshifts would correspond to distances $d \simeq 122.2$ Mpc, $d \simeq 1.2$ Gpc, $d \simeq 2.4$ Gpc, $d \simeq 3.5$ Gpc, respectively. In these simulations we are taking into account the redshift effects discussed in Subsection 3.5. To obtain the probability distributions, we have performed 10^4 simulations of the photon evolution within the random magnetic field configurations. For simplicity, we have assumed that in each simulation all sources have the same initial linear polarization, $\Pi_0 = 0.0, 0.3, 0.7, 1.0$, respectively. It turns out that photon-ALP mixing smears out the initial GRB linear polarization. This effect increases with the source distance and saturates at $z \simeq 2$. For $z \lesssim 1$, f_Π still presents a peak which is the relic of the initial linear polarization, but with long tails which are not present in the standard polarization distributions described in Section 2. In particular, the expected clustering in the linear

Figure 2. Average linear polarization Π_L (dotted line) and photon survival probability $P_{\gamma\gamma}$ evaluated numerically (dashed line) and analytically (solid line), as a function of the source distance d for photon-ALP mixing in the extragalactic magnetic field. The source is assumed to be fully polarized along the x direction.

polarization distributions gets smeared out by photon-ALP mixing. Moreover, since the standard GRB linear polarization should have an initial spread and the GRBs are actually distributed over a variety of distances, in the presence of photon-ALP mixing the final distributions should to be even more smeared out and irregular than the ones presented in these Figures. For $z \gtrsim 1$ we find rather flat probability distributions in the GRB polarizations, without any record of the initial linear polarization Π_0 . As a consequence, the presence of photons-ALP mixing appears to hinder the possibility to extract from observational data information on the initial polarization mechanism for GRBs. Conversely – in the lack of any standard explanation – detection of the features presented above can be interpreted as a hint at the existence of very light ALPs.

4.3. Intracluster magnetic fields

Given that GRBs are at cosmological distances, there is a nontrivial chance that in some cases their line of sight crosses a cluster of galaxies. So, it is worthwhile to investigate what happens in this instance.

Figure 3. Probability density function f_{Π} for the final linear polarization Π_L after propagation in the extragalactic magnetic field, considering 10^4 GRBs at redshift $z = 0.03$, with initial linear polarization $\Pi_0 = 0.0, 0.3, 0.7, 1.0$.

Observations have shown that the presence of magnetic fields with average strength $B \simeq 10^{-6}$ G is a typical feature of the intracluster region. Even more remarkable is the fact that observations are able to yield information about the associated coherence length, which turns out to be $L \simeq 10$ kpc [66]. As in the case of extragalactic magnetic fields, we assume a cellular structure for the intracluster fields, with domain size $L \simeq 10$ kpc. As before, plasma effects are expected to be present. Specifically, the electron density in the intracluster medium is $n_e \simeq 1.0 \times 10^{-3} \text{ cm}^{-3}$ [67], yielding a plasma frequency $\omega_{\text{pl}} \simeq 1.2 \times 10^{-12}$ eV.

With these input values, the low-energy cut-off E_L in Eq. (26) is $E_L \simeq 3.6$ keV for $m < 10^{-12}$ eV, thereby guaranteeing that for our benchmark values $E = 100$ keV and $m = 10^{-13}$ eV we are in the strong-mixing regime, where the photon-ALP conversion probability is energy-independent.

In Figure 7 we plot the average linear polarization Π_L and the photon survival probability $P_{\gamma\gamma}$ as a function of the distance D traveled inside the intracluster region, assuming that the source is fully polarized along the x direction. The averaging process is again over an ensemble of 10^4 realizations of the random magnetic field network. We

Figure 4. Probability density function f_{Π} for the final linear polarization Π_L after propagation in the extragalactic magnetic field, considering 10^4 GRBs at redshift $z = 0.3$, with initial linear polarization $\Pi_0 = 0.0, 0.3, 0.7, 1.0$.

find that for $D \gtrsim 200$ kpc both the polarization and the survival probability saturate at their limiting values, $P_{\gamma\gamma} = 2/3$ and $\Pi_L \simeq 0.79$ respectively.

As before, the source dimming turns out to be unimportant. Thus, the result for the average final polarization shown in Figure 7 implies that whenever the line of sight to a GRB crosses a cluster of galaxies the polarization distributions shown in Figures 3, 4, 5 and 6 are expected to be further smeared out.

4.4. Galactic magnetic fields

Finally, the beam from a GRB obviously crosses the Milky Way before being detected. Observations over the last three decades have led to a rather detailed picture of the Milky Way magnetic field. Perhaps, its most important feature is that it consists of two components, a regular and a turbulent one. We proceed to address the ALP-induced polarization and the photon-ALP conversion in these two magnetic field configurations.

Regular component – Measurements of the Faraday rotation based on pulsar observations have shown that this component is parallel to the Galactic plane. Its strength varies between $B \simeq 2 \times 10^{-6}$ G in the Solar neighborhood and $B \simeq 4 \times 10^{-6}$ G

Figure 5. Probability density function f_{Π} for the final linear polarization Π_L after propagation in the extragalactic magnetic field, considering 10^4 GRBs at redshift $z = 1$, with initial linear polarization $\Pi_0 = 0.0, 0.3, 0.7, 1.0$.

at 3 kpc from the center [68]. Moreover, the associated coherence length is $L \simeq 10$ kpc. Inside the Milky Way disk the electron density is $n_e \simeq 1.1 \times 10^{-2} \text{ cm}^{-3}$ [69], resulting in a plasma frequency $\omega_{\text{pl}} \times 4.1 \times 10^{-12} \text{ eV}$. Assuming the whole Galaxy as a single domain with an homogeneous magnetic field, for these input values Eq. (26) entails $E_L \simeq 10 \text{ keV}$ for $m < 10^{-12} \text{ eV}$, so that for our reference values $E = 100 \text{ keV}$ and $m = 10^{-13} \text{ eV}$ we are in the strong-mixing regime. In Figure 8 we show the linear polarization Π_L and the photon survival probability $P_{\gamma\gamma}$ as a function of the photon path D in the Galaxy, taking as Galactic magnetic field $B \simeq 4 \times 10^{-6} \text{ G}$, oriented along the y direction. Both quantities depend on the initial photon polarization. In the left panel we have chosen the initial linear polarization along the y axis. In this situation, we find a final survival probability $P_{\gamma\gamma} \simeq 0.68$, while the initial linear polarization $\Pi_L = 1$ remains unchanged. Instead, in the right panel we have started our simulation with a completely unpolarized state ($\Pi_L = 0$). In this case, the photon-ALP conversion produces sizeable effects on both the photon flux and the photon polarization. In particular, the survival probability after Galaxy crossing is $P_{\gamma\gamma} \simeq 0.84$ and the final linear polarization $\Pi_L \simeq 0.19$. A detailed study of this effect would require a better modelling of the Galactic magnetic field, as

Figure 6. Probability density function f_{Π} for the final linear polarization Π_L after propagation in the extragalactic magnetic field, considering 10^4 GRBs at redshift $z = 2$, with initial linear polarization $\Pi_0 = 0.0, 0.3, 0.7, 1.0$.

in the study of photon-ALP conversion in the Milky Way performed in [70]. However, we leave further refinements of these estimates for future work.

Turbulent component – Over much smaller scales, the dominant Galactic magnetic field appears to be stochastic, with a Kolmogorov spectrum $\alpha = 5/3$ [71]. In practice, this component can be described by a cellular structure, with strength $B \simeq 1 \times 10^{-6}$ G and domain size $L \simeq 10^{-2}$ pc. It is straightforward to realize that in this case the oscillation length $l_{\text{osc}} = 2\pi/\Delta_{\text{osc}}$ is much larger than the domain size L , so that the photon-ALP conversion is vanishingly small.

5. Conclusions

Measuring the polarization of prompt GRB emission in the keV-MeV range represents one of the main challenges for high-energy astronomy of the next decade. Various polarimetric missions are currently being developed, which are expected to collect an all-sky rich sample of GRBs so as to allow for a meaningful statistical analysis of their polarization properties. As recently realized, important conclusions concerning the GRB

Figure 7. Average linear polarization Π_L (dotted line) and photon survival probability $P_{\gamma\gamma}$ (dashed line) as a function of the distance D traveled inside the intracluster region. The source is assumed to be fully polarized along the x direction.

emission models are expected to be drawn from these studies.

We have shown that the existence of ALPs with parameters lying in experimentally allowed ranges drastically modifies the GRB polarization pattern. More specifically, cosmic magnetic fields of extragalactic, intracluster and Galactic origin along the line of sight to a GRB act as catalysts for significant photon-ALP mixing. In particular, due to the random structure of the extragalactic and intracluster magnetic fields, the amount of photon-ALP mixing strongly depends on the orientation of the line of sight. Therefore, starting with a given source polarization a broad statistical distribution is expected to be detected when observing GRBs from different directions in the sky. This effect should be superimposed on the original distribution of the GRB polarization as predicted by standard emission models. As a result, the scatter in the distribution arising from the photon-ALP mixing hinders the possibility to extract information on the initial polarization for the observed GRBs. Alternatively, in the lack of any standard explanation, the observation of these peculiar broad distributions would hint at the existence of very light ALPs. We have restricted throughout our attention to the linear polarization because in all cases that we have analyzed the circular polarization turns out

Figure 8. Linear polarization Π_L (solid curve) and survival probability $P_{\gamma\gamma}$ (dashed curve) for the photon-ALP mixing in the regular component of the Galactic magnetic field as a function of the photon path D in the Galaxy. We have assumed photons to be fully polarized along the y direction (left panel) or completely unpolarized (right panel) before entering the Galaxy. We have taken as Galactic magnetic field $B = 4 \times 10^{-6}$ G, oriented along the y axis.

to be vanishingly small. This circumstance is at variance with the case of chameleontic ALPs [35], and so it can be used to further investigate the nature of ALPs.

In the last few years, different hints and possible signatures of very light ALPs have been proposed in connection with astrophysical observations [54, 55, 65, 70, 72, 73, 74, 75, 76, 77, 78]. In general, the presence of ALPs can play a role for values of the photon-ALP coupling constant $g_{a\gamma} \lesssim 10^{-11} \text{ GeV}^{-1}$, namely one order of magnitude lower than the current experimental limit set by the CAST experiment. This indicates the high potential of astrophysical observations to probe ALPs in a region of their parameter space otherwise unreachable. It remains to see whether the above hints at ALPs will ultimately converge in a robust signature. Every astrophysical argument has its own systematic uncertainties and its own recognized or unrecognized loop-holes, so that in order to corner the ALPs it is important to use as many independent channels and as many different approaches as possible. In this sense, we believe that the present study of ALP effects on the GRB polarization should be regarded as an additional opportunity to uncover the existence of very light ALPs through astrophysical observations. Remarkably enough, no dedicated experiment is required and our predictions can be easily tested in the near future with the planned polarimetric missions for GRBs.

Acknowledgments

We would like to thank Enrico Costa, Gabriele Ghisellini and Kenji Toma for discussions about the possibility to measure the polarization of distant high-energy astrophysical sources in a systematic fashion. M. R. also thanks the Dipartimento di Fisica Nucleare e Teorica, Università di Pavia, for support.
